CHAPTER 2
Evidence-Based Public Health

LEARNING OBJECTIVES

By the end of this chapter, the student will be able to:

- explain the steps in the evidence-based public health process.
- describe a public health problem in terms of morbidity and mortality.
- describe the course of a disease in terms of incidence, prevalence, and case-fatality.
- describe how the distribution of disease may be used to generate hypotheses about the cause of a disease.
- describe an approach used in public health to identify a contributory cause of a disease or other condition and establish the efficacy of an intervention.
- describe the uses of qualitative data that complement quantitative data.
- describe the process of grading evidence-based recommendations.
- use an approach to identify options for intervention based on “when, who, and how.”
- explain the role that evaluation plays in establishing effectiveness as part of evidence-based public health.

Tobacco was introduced to Europe as a new world crop in the early 1600s. Despite the availability of pipe tobacco and, later, cigars, the mass production and consumption of tobacco through cigarette smoking did not begin until the development of the cigarette rolling machine by James Duke in the 1880s. This invention allowed mass production and distribution of cigarettes for the first time. Men were the first mass consumers of cigarettes. During World War I, cigarettes were widely distributed free of charge to U.S. soldiers. Cigarette smoking first became popular among women in the 1920s—an era noted for changes in the role and attitudes of women—and at this time, advertising of cigarettes began to focus on women. The mass consumption of cigarettes by women, however, trailed that of men by at least two decades. By the 1950s, over 50% of adult males and approximately 25% of adult females were regular cigarette smokers.

The health problems of cigarette smoking were not fully recognized until decades after the habit became widespread. As late as the 1940s, R.J. Reynolds advertised that “more doctors smoke Camels than any other cigarette.”

Epidemiologists observed that lung cancer deaths were increasing in frequency in the 1930s and 1940s. The increase in cases did not appear to be due to changes in efforts to recognize the disease, the ability to recognize the disease, or the definition of the disease. Even after the increasing average life span and aging of the population was taken into account, it was evident that the rate
of death from lung cancer was increasing—and more rapidly for men than women. In addition, it was noted that residents of states with higher rates of smoking had higher rates of lung cancer. In the 1950s, the number of lung cancer deaths in females also began to increase, and by the 1960s, the disease had become the most common cause of cancer-related deaths in males and was still rising among women.\(^3\)\(^,\)\(^2\)

This type of information was the basis for describing the problems of cigarette smoking and lung cancer and developing ideas or hypotheses about its etiology, or cause. Let us take a look at how the evidence-based public health approach has been used to address the problem of cigarette smoking. There are five basic questions that we need to ask that together make up what we will call the evidence-based public health approach.\(^3\)

1. **Problem:** What is the health problem?
2. **Etiology:** What is/are the contributory cause(s)?
3. **Recommendations:** What works to reduce the health impacts?
4. **Implementation:** How can we get the job done?
5. **Evaluation:** How well does/do the intervention(s) work in practice?

These five questions provide a framework for defining, analyzing, and addressing a wide range of public health issues and can be applied to cigarette smoking for the purposes of this chapter.\(^4\) We will call this framework the **P.E.R.I.E. process.** This process is actually circular, as illustrated in **FIGURE 2.1.** If the evaluation suggests that more needs to be done, the cycle can and should be repeated. Thus, it is an ongoing process.

Using cigarette smoking as an example, we will illustrate the steps needed to apply the evidence-based public health approach.

### How Can We Describe a Health Problem?

In describing a health problem, we need to address the burden, course, and distribution of disease. The first step in addressing a health problem is to describe its **burden of disease,** which is the occurrence of disability and death due to a disease. In public health, disability is often called **morbidity** and death is called **mortality.** We will want to know the current burden of disease and whether there has been a recent change in the burden of the disease.

In addition to describing the burden of disease, it is important to describe what we call the **course of a disease.** The course of the disease asks how often the disease occurs, how likely it is to be present currently, and what happens once it occurs. Describing the course of a disease as well as the burden of disease requires us to use measurements known as rates. **BOX 2.1** discusses what we mean by “rates” and how we can use them to describe the burden and course of disease.

In addition to describing the burden and the course of a disease or other health problem, we need to ask: What is the **distribution of disease?** Distribution of disease asks such questions as: Who gets the disease? Where are they located? When does the disease occur? Let us see how understanding the
The term "rate" is often used to describe any type of measurement that has a numerator and a denominator where the numerator is a subset of the denominator—that is, the numerator includes only individuals who are also included in the denominator. In a rate, the numerator measures the number of times an event, such as the diagnosis of lung cancer, occurs. The denominator measures the number of times the event could occur. We often use the entire population in the denominator, but at times, we may only use the at-risk population. For instance, when measuring the rate of cervical cancer, we would only use the population of women in the denominator, and when measuring rates of prostate cancer, we would only use the population of men in the denominator.

There are two basic types of rates that are key to describing a disease. These are called incidence rates and prevalence. Incidence rates measure the chances of developing a disease over a period of time—usually one year. That is, incidence rates are the number of new cases of a disease that develop during a year divided by the number of people in the at-risk population at the beginning of the year, as in the following equation:

\[
\text{Incidence rate} = \frac{\text{# of new cases of a disease in a year}}{\text{# of people in the at-risk population}}
\]

We often express incidence rates as the number of events per 100,000 people in the denominator. For instance, the incidence rate of lung cancer might be 100 per 100,000 per year. In evidence-based public health, comparing incidence rates is often a useful starting point when trying to establish the etiology, or cause, of a problem.

Mortality rates are a special type of incidence rate that measure the incidence of death due to a disease during a particular year. Mortality rates are often used to measure the burden of disease. When most people who develop a disease die from the disease, as is the situation with lung cancer, the mortality rate and the incidence rates are very similar. Thus, if the incidence rate of lung cancer is 100 per 100,000 per year, the mortality rate might be 95 per 100,000 per year. When mortality rates and incidence rates are similar and mortality rates are more easily or reliably obtained, epidemiologists may substitute mortality rates for incidence rates. The relationship between the incidence rate and the mortality rate is important because it estimates the chances of dying from the disease once it is diagnosed. We call this the case-fatality. In our example, the chances of dying from lung cancer—the mortality rate divided by the incidence rate—is 95%, which indicates that lung cancer results in a very poor prognosis once it is diagnosed.

Prevalence is the number of individuals who have a disease at a particular time divided by the number of individuals who could potentially have the disease. It can be represented by the following equation:

\[
\text{Prevalence} = \frac{\text{# of living with a particular disease}}{\text{# of people in the at-risk population}}
\]

Thus, prevalence tells us the proportion of individuals who have the disease at a point in time.

Despite the fact that lung cancer has become the most common cancer, the prevalence will be low—perhaps one-tenth of 1% or less—because those who develop lung cancer do not generally live for a long period of time. Therefore, you will rarely see people with lung cancer. The prevalence of chronic diseases of prolonged duration, such as asthma or chronic obstructive pulmonary disease (COPD), is often relatively high; hence you will often see people with these diseases.

Prevalence is often useful when trying to assess the total impact or burden of a health problem in a population and can help identify the need for services. For example, knowledge that there is a high prevalence of lung cancer in a certain region may indicate that there is a need for special types of healthcare services in that area.

---

a When talking about the term "rate," many epidemiologists also include a unit of time, such as a day or a year, over which the number of events in the numerator is measured. This may also be called a true rate. The term "rate" as used in this text includes true rates, as well as proportions. A proportion is a fraction in which the numerator is a subset of the denominator. A time period is not required for a proportion; however, it often reflects the situation at one point in time.

b This is an example of the pragmatic approach that is often taken by epidemiologists when they are limited by the available data. The question facing epidemiologists is frequently: Is the data good enough to address the question? Thus, epidemiology can be thought of as an approximation science.

c The relationship between incidence and prevalence rates is approximately the incidence rate \( \times \) average duration of the disease = the prevalence rate. Both the incidence rate and the average duration affect the prevalence of the disease. Together, the incidence, prevalence, and case-fatality rates provide a population-based summary of the course of a disease. Incidence reflects the chance of developing the disease; prevalence indicates the chances of having the disease; and case-fatality indicates the prognosis or chance of dying from the disease.
How Can Understanding Distribution of Disease Help Generate Hypotheses About the Cause Of Disease?

Public health professionals called **epidemiologists** investigate factors known as “person” and “place” to see if they can find patterns or **associations** in the frequency of a disease. We call these **group associations** or ecological associations. Group associations may suggest ideas or hypotheses about the cause, or etiology, of a disease.

“Person” includes demographic characteristics that describe people, such as age, gender, race, and socioeconomic factors. It also includes behaviors or exposures, such as cigarette smoking, exercise, radiation exposure, and use of medications. “Place” traditionally implies geographic location, such as a city or state. Place matters in the occurrence of disease. The term “healthography” has recently been introduced to reflect the importance of geographic location to health. Place also includes nonphysical connections between people, such as a university community or a shared Internet site. When these types of factors occur more frequently among groups with the disease than among groups without the disease, we call them **risk indicators** or risk markers.\(^a\)

**BOX 2.2** illustrates how person and place can be used to generate hypotheses about the cause of a disease.

In looking at the distribution of lung cancer and the potential risk factors, epidemiologists found some important relationships. In terms of person, the increases in lung cancer mortality observed in the 1930s–1950s were far more dramatic among men than among women, though by the 1950s, the mortality rate among women had begun to increase as well. It was noted that cigarette use had increased first in men and later among women. There appeared to be a delay of several decades between the increase in cigarette smoking and the increase in lung cancer mortality among both men and women. This illustrates that “time” along with “person” and “place” is important in generating hypotheses.

In terms of place, it was found that the relationship between cigarette smoking and lung cancer mortality was present throughout the United States, but was strongest in those states where cigarette smoking was most common. Therefore, changes over time and the distribution of disease using person and place led epidemiologists to the conclusion that there was an association between groups of people who smoked more frequently and the same group’s mortality rates due to lung cancer. These relationships generated the idea that cigarettes might be a cause of lung cancer.

It is important to realize that these mortality rates are group rates. These data did not include any information about whether those who died from lung cancer were smokers. It merely indicated that groups who smoked more, such as males, also had higher mortality rates from lung cancer. The most that we can hope to achieve from these data is to generate hypotheses based on associations between groups, or group associations. When we try to establish causation or etiology, we will need to go beyond group association and focus on associations at the individual level.

Finally, epidemiologists take a scientific approach to addressing public health problems. They are often skeptical of initial answers to a question and ask: Could there be another explanation for the differences or changes in the distribution of disease?

\(^a\) The term “risk indicator” or “risk marker” needs to be distinguished from the term “risk factor.” A risk factor is a candidate for being a contributory cause and implies that at least an association at the individual level has been established.
**BOX 2.2 Generating Hypotheses from Distributions of Person and Place**

An increased frequency of disease based upon occupation has often provided the initial evidence of a group association based upon a combination of “person” and “place.” The first recognized occupational disease was found among chimney sweeps often exposed for long periods of time to large quantities of coal dust and who were found to have a high incidence of testicular cancer.

The Mad Hatter described in *Alice’s Adventures in Wonderland* by Lewis Carroll made infamous the 19th-century recognition that exposure to mercury fumes was associated with mental changes. Mercury fumes were created when making the felt used for hats; hence the term “mad as a hatter.”

The high frequency of asbestosis among those who worked in shipyards suggested a relationship decades before the dangers of asbestos were fully recognized and addressed. A lung disease known as silicosis among those who worked in the mining industry likewise suggested a relationship that led to an in-depth investigation and greater control of the risks.

More recently, a rare tumor called angiosarcoma was found to occur among those exposed over long periods to polyvinyl chloride (PVC), a plastic widely used in construction. The initial report of four cases of this unusual cancer among workers in one PVC plant was enough to strongly suggest a cause-and-effect relationship based upon place alone.

An important example of the impact that place can have on generating ideas or hypotheses about causation is the history of fluoride and cavities. In the early years of the 1900s, children in the town of Colorado Springs, CO, were found to have a very high incidence of brown discoloration of the teeth. It was soon recognized that this condition was limited to those who obtained their water from a common source. Ironically, those with brown teeth were also protected from cavities. This clear relationship to place was followed by over two decades of research that led to the understanding that fluoride in the water reduces the risk of cavities, while very high levels of the compound also lead to brown teeth. Examination of the levels of fluoride in other water systems eventually led to the establishment of levels of fluoride that could protect against cavities without producing brown teeth.

Such strong and clear-cut relationships are important, but relatively unusual. Often, examinations of the characteristics of person and place in populations suggest hypotheses that can be followed up among individuals to establish cause-and-effect relationships.4,5

### How Do Epidemiologists Investigate Whether There Is Another Explanation for the Difference or Changes in the Distribution of Disease?

Epidemiologists ask: Are the differences or changes real or are they **artificial**? There are three basic reasons that changes in rates may be artificial rather than real:

- Differences or changes in the interest in identifying the disease
- Differences or changes in the ability to identify the disease
- Differences or changes in the definition of the disease

For some conditions, such as HIV/AIDS, these changes have all occurred. New and effective treatments have increased the interest in detecting the infection. Improved technology has increased the ability to detect HIV infections at an earlier point in time. In addition, there have been a number of modifications of the definition of AIDS based on new opportunistic infections and newly recognized complications. Therefore, with HIV/AIDS, we need to be especially attentive to the possibility that artificial changes have occurred.

In describing the distribution of a problem, epidemiologists ask: Are the differences or changes used to suggest group associations and generate hypotheses artificial or real?

Let us see how this applies to our lung cancer example. As we have seen, lung cancer is a disease with a very poor prognosis; therefore, the burden of disease is high as measured by its high mortality rate. This was the situation in the past and to a large extent continues to be the situation.

Mortality rates have been obtained from death certificates for many years. The cause of death on death certificates is classified using a standardized coding system known as the International Classification of Diseases (ICD). No equally complete or accurate system has been available for collecting data on the incidence rates of lung cancer. However, as we
Evidence developed. There was a need for more long-term exposure to cigarettes before lung cancer. Epidemiologists had concluded from the study of death certificates that lung cancer deaths were rapidly increasing. By the 1930s, epidemiologists look at the rates of the disease in each age group and also the age distribution, or the number of people in each age group in the population. Then they combine the rates for each age group, taking into account or adjusting for the age distribution of a population. Taking into account the older average age of the population in 1960 compared to 1930 slightly reduced the apparent increase in lung cancer but large differences between 1930 and 1960 remained. As a result, epidemiologists concluded that lung cancer mortality rates changed over this period, especially among men; the changes in rates were real; and the changes could not be explained simply by the aging of the population. Thus, epidemiologists established the existence of a group association between groups that smoked more cigarettes and groups that developed lung cancer.

**BOX 2.3 Age Adjustment**

Despite the existence of a real change in the rates of lung cancer between 1930 and 1960, it was still possible that the increased mortality rates from lung cancer were due to the increasing life span that was occurring between 1930 and 1960, leading to the aging of the population and an older population, on average. Perhaps older people are more likely to develop lung cancer and the aging of the population itself explains the real increase in the rates. To address this issue, epidemiologists use what is called age adjustment. To conduct age adjustment, epidemiologists look at the rates of the disease in each age group and also the age distribution of the population. The age distribution of the U.S. population in 2000 is currently used as the standard population. Adjustment is not limited to age and may at times be conducted using other characteristics that may differ among the groups, such as gender or race, which may affect the probability of developing a disease.

Adjustment for age is often performed by combining the rates in each age group using the age distribution of a standard population. The age distribution of the U.S. population in 2000 is currently used as the standard population. Adjustment is not limited to age and may at times be conducted using other characteristics that may differ among the groups, such as gender or race, which may affect the probability of developing a disease.

Learned in our discussion of rates, the incidence rates and mortality rates for lung cancer are very similar. Therefore, we can use mortality data as a substitute for incidence data when evaluating the overall burden of lung cancer in a population. By the 1930s, epidemiologists had concluded from the study of death certificates that lung cancer deaths were rapidly increasing. This increase continued through the 1950s—with the increase in lung cancer occurring two decades or more after the increase in consumption of cigarettes. Therefore, it was not immediately obvious that the two were related. In order to hypothesize that cigarettes are a cause of lung cancer, one needed to conclude that there was a long delay and/or a need for long-term exposure to cigarettes before lung cancer developed. There was a need for more evidence linking cigarettes and lung cancer.

From the 1930s through the 1950s, a large number of studies established that lung cancer deaths were increasing among men, but not among women. That is, there was a change over time and a difference between groups. Epidemiologists, therefore, considered whether the changes or differences in rates were real, or whether they could be artificial or artifactual.

With lung cancer, the diagnosis at the time of death has been of great interest for many years. The ability to diagnose the disease has not changed substantially over the years. In addition, the use of ICD codes on death certificates has helped standardize the definition of the disease. Epidemiologists concluded that it was unlikely that changes in interest, ability, or definition explained the changes in the rates of lung cancer observed in males, thus they concluded that the changes were not artifactual, but real.

**BOX 2.3** discusses age adjustment, which is one additional step that epidemiologists frequently make when looking at rates.

**What Is the Implication of a Group Association?**

Group associations are established by investigations that use information on groups or a population without having information on the specific individuals within the group. These studies have been called population comparisons or ecological studies. Having established the existence of a group association, we still do not know if the individuals who smoke cigarettes are the same ones who develop lung cancer. We can think of a group association as a hypothesis that requires investigation at the individual level.
level. The group association between cigarettes and lung cancer was the beginning of a long road to establish that cigarettes are a cause of lung cancer.

Not all group associations are also individual associations. Imagine the following situation: the mortality rates from drowning are higher in southern states than in northern states in the United States. The per capita consumption of ice cream is also higher in southern states than in northern states. Thus, a group association was established between ice cream consumption and drowning. In thinking about this relationship, you will soon realize that there is another difference between southern and northern states. The average temperature is higher in southern states, and higher temperatures are most likely associated with more swimming and also more ice cream consumption. Ice cream consumption is therefore related both to swimming and to drowning. We call this type of factor a possible confounding variable. In this situation, there is no evidence that those who drown actually consumed ice cream. That is, there is no evidence of an association at the individual level. Thus, group associations can be misleading if they suggest relationships that do not exist at the individual level.

Epidemiology research studies that look at associations at the individual level are key to establishing etiology, or cause. Etiology is the second component of the P.E.R.I.E. approach. Let us turn our attention to how to establish etiology.

**Etiology: How Do We Establish Contributory Cause?**

Understanding the reasons for disease is fundamental to the prevention of disability and death. We call these reasons etiology or causation. In evidence-based public health, we use a very specific definition of causation—contributory cause. The evidence-based public health approach relies on epidemiological research studies to establish a contributory cause. This requires that we go beyond group association and establish three definitive requirements:

1. The “cause” is associated with the “effect” at the individual level. That is, the potential “cause” and the potential “effect” occur more frequently in the same individual than would be expected by chance. Therefore, we need to establish that individuals with lung cancer are more frequently smokers than individuals without lung cancer.

   The “cause” precedes the “effect” in time. That is, the potential “cause” is present at an earlier time than the potential “effect.” Therefore, we need to establish that cigarette smoking comes before the development of lung cancer.

2. Altering the “cause” alters the “effect.” That is, when the potential “cause” is reduced or eliminated, the potential “effect” is also reduced or eliminated. Therefore, we need to establish that reducing cigarette smoking reduces lung cancer rates.

**BOX 2.4** illustrates the logic behind using these three criteria to establish a cause-and-effect relationship, as well as the implications of a contributory cause.

These three definitive requirements may be established using three different types of studies, all of which relate potential “causes” to potential “effects” at the individual level. That is, they investigate whether individuals who smoke cigarettes are the same individuals who develop lung cancer. The three basic types of investigations are called case-control studies, cohort studies, and randomized controlled trials.

Case-control studies are most useful for establishing requirement number one; that is, the “cause” is associated with the “effect” at the individual level. Case-control studies can demonstrate that cigarettes and lung cancer occur together more frequently than would be expected by chance alone. To accomplish this, cases with the disease (lung cancer) are compared to controls without the disease to determine whether the cases and the controls previously were exposed to the potential “cause” (cigarette smoking).
The requirements for establishing the type of cause-and-effect relationship known as contributory cause used in evidence-based public health can be illustrated by the cause-and-effect relationship between lightning and thunder that human beings have recognized from the earliest times of civilization.

First, lightning is generally associated with thunder; that is, the two occur together far more often than one would expect if there were no relationship. Second, with careful observation, it can be concluded that the lightning is seen a short time before the thunder is heard. That is, the potential “cause” (the lightning) precedes in time the “effect” (the thunder). Finally, when the lightning stops, so does the thunder—thus, altering the “cause” alters the “effect.”

Notice that lightning is not always associated with thunder. Heat lightning may not produce audible thunder, or the lightning may be too far away for the thunder to be heard. Lightning is not sufficient in and of itself to guarantee that our ears will subsequently always hear thunder. Conversely, it has been found that the sound of thunder does not always require lightning. Other reasons for the rapid expansion of air, such as an explosion or volcanic eruption, can also create a sound similar or identical to thunder.

The recognition of lightning as a cause of thunder came many centuries before human beings had any understanding of electricity or today’s appreciation for the science of light and sounds. Similarly, cause-and-effect relationships established by epidemiological investigations do not always depend on understanding the science behind the relationships.

When a factor such as cigarettes has been demonstrated to be associated on an individual basis with an outcome such as lung cancer, we often refer to that factor as a risk factor.¹

During the 1940s and early 1950s, a number of case-control studies established that individuals who developed lung cancer were far more likely to be regular smokers compared to similar individuals who did not smoke cigarettes. These case-control studies established requirement number one—the “cause” is associated with the “effect” at the individual level. They established that cigarettes are a risk factor for lung cancer.

Cohort studies are most useful for establishing requirement number two—the “cause” precedes the “effect.” Those with the potential “cause” or risk factor (cigarette smoking) and those without the potential “cause” are followed over time to determine who develops the “effect” (lung cancer).²

Several large scale cohort studies were conducted in the late 1950s and early 1960s. One conducted by the American Cancer Society followed nearly 200,000 individuals over 3 or more years to determine the chances that smokers and nonsmokers would develop lung cancer. Those who smoked regularly at the beginning of the study had a greatly increased chance of developing lung cancer over the course of the study; thus, establishing requirement number two, the “cause” precedes the “effect” in time.

Randomized controlled trials are most useful for establishing requirement number three—altering the “cause” alters the “effect.” Using a chance process known as randomization or random assignment, individuals are assigned to be exposed or not exposed to the potential “cause” (cigarette smoking). Individuals with and without the potential “cause” are then followed over time to determine who develops the “effect.”

Conducting a randomized controlled trial of cigarettes and lung cancer would require investigators to randomize individuals to smoke cigarettes or not smoke cigarettes and follow them over many years. This illustrates the obstacles that can occur in seeking to definitively establish contributory cause. Once there was a strong suspicion that cigarettes might cause lung cancer, randomized controlled trials were not practical or ethical as a method for establishing cigarette smoking as a contributory cause of lung cancer. Therefore, we need to look at additional supportive or

---

¹ A risk factor, as we just discussed, usually implies that the factor is associated with the disease at the individual level. At times, it may be used to imply that the factor not only is associated with the disease at the individual level, but that it precedes the disease in time. Despite the multiple uses of the term, a risk factor does not in and of itself imply that a cause-and-effect relationship is present, though it may be considered a possible cause.

² It may seem obvious that cigarette smoking precedes the development of lung cancer. However, the sequence of events is not always so clear. For instance, those who have recently quit smoking cigarettes have an increased chance of being diagnosed with lung cancer. This may lead to the erroneous conclusion that stopping cigarette smoking is a cause of lung cancer. It is more likely that early symptoms of lung cancer lead individuals to quit smoking. The conclusion that stopping cigarette smoking causes lung cancer is called reverse causality. Thus, it was important that cohort studies followed smokers and nonsmokers for several years to establish that the cigarette smoking came first.
ancillary criteria that we can use to help us establish the existence of contributory cause.\footnote{At times, a special form of a cohort study called a natural experiment can help establish that altering the cause alters the effect. A natural experiment implies that an investigator studies the results of a change in one group, but not in another similar group that was produced by forces outside the investigator's control. For instance, after the surgeon general's 1964 Report on Smoking and Health was released, approximately 100,000 physicians stopped smoking. This did not happen among other professionals. Over the next decade, the rates of lung cancer among physicians dropped dramatically, but not among other professionals. Despite the fact that natural experiments can be very useful, they are not considered as reliable as randomized controlled trials. Randomization, especially in large studies, eliminates differences between groups or potential confounding differences, even when these differences in characteristics are not recognized by the investigators.}

\textbf{Figure 2.2} illustrates the requirements for definitively establishing contributory cause and the types of studies that may be used to satisfy each of the requirements. Notice that the requirements for establishing contributory cause are the same as the requirements for establishing efficacy. Efficacy implies that an intervention works; that is, it increases positive outcomes or benefits in the population being investigated.

\section*{What Can We Do If We Cannot Demonstrate All Three Requirements to Definitively Establish Contributory Cause?}

When we cannot definitively establish a contributory cause, we often need to look for additional supportive evidence.\footnote{In evidence-based public health we often utilize what have been called supportive or ancillary criteria to make scientific judgments about cause and effect. A large number of these criteria have been used and debated. However, four of them are widely used and pose little controversy. They are:}

\begin{itemize}
  \item Strength of the relationship
  \item Dose-response relationship
  \item Consistency of the relationship
  \item Biological plausibility
\end{itemize}

Let us examine what we mean by each of these criteria.

The \textbf{strength of the relationship} implies that we are interested in knowing how closely related the risk factor (cigarette smoking) is to the disease (lung cancer). In other words, we want to know the probability of lung cancer among those who smoke cigarettes compared to the probability of lung cancer among those who do not smoke cigarettes. To measure the strength of the relationship, we calculate what we call the \textbf{relative risk}. The relative risk is the probability of developing the disease if the risk factor is present compared to the probability of developing the disease if the risk factor is not present. Therefore, the relative risk for cigarette smoking is calculated as:

\begin{equation*}
\text{Relative risk} = \frac{\text{Probability of lung cancer for cigarette smokers}}{\text{Probability of lung cancer of nonsmokers}}
\end{equation*}
The relative risk for cigarette smoking and lung cancer is approximately 10. A relative risk of 10 is very large. It tells us that the chances or probability of developing lung cancer are 10 times as great for the average smoker compared to the average nonsmoker.1

In addition to looking at the strength of the overall relationship between smoking cigarettes and lung cancer, we can ask whether smoking more cigarettes is associated with a greater chance of developing lung cancer. If it is, then we say there is a dose-response relationship. For instance, smoking one pack of cigarettes per day over many years increases the chances of developing lung cancer compared to smoking half a pack per day. Similarly, smoking two packs per day increases the chances of developing the disease compared to smoking one pack per day. These examples show that a dose-response relationship is present.6

Consistency implies that studies in different geographic areas and among a wide range of groups produce similar results. A very large number of studies of cigarettes and lung cancer in many countries and among those of nearly every race and socioeconomic group have consistently demonstrated a strong individual association between cigarette smoking and lung cancer.

The final supportive criterion is biological plausibility. This term implies that we can explain the occurrence of disease based upon known and accepted biological mechanisms. We can explain the occurrence of lung cancer by the fact that cigarette smoke contains a wide range of potentially toxic chemicals that reach the locations in the body where lung cancer occurs.

The ancillary criteria add support to the argument that cigarette smoking is a contributory cause of lung cancer. TABLE 2.1 summarizes the use of ancillary or supportive criteria in making scientific judgments about contributory cause and illustrates these principles using the cigarette smoking and lung cancer scenario. It also cautions us to use these criteria carefully because a cause-and-effect relationship may be present even when some or all of these criteria are not fulfilled.6

We have now summarized the approach used in evidence-based public health to establish a contributory cause. We started with the development of group associations that generate hypotheses and moved on to look at the definitive requirements for establishing contributory cause. We also looked at the ancillary or supportive criteria that are often needed to make scientific judgments about contributory cause. TABLE 2.2 summarizes this process and applies it to cigarette smoking and lung cancer.

What Does Contributory Cause Imply?

Establishing a contributory cause on the basis of evidence is a complicated and often time-consuming job. In practice, our minds often too quickly jump to the conclusion that a cause-and-effect relationship exists. Our language has a large number of words that may subtly imply a cause-and-effect relationship, even in the absence of evidence. BOX 2.5 illustrates how we often rapidly draw conclusions about cause and effect.

It is important to understand what the existence of a contributory cause implies and what it does not imply. Despite the convincing evidence that cigarette smoking is a contributory cause of lung cancer, some individuals never smoke and still develop lung cancer. Therefore, cigarettes are not what we call a necessary cause of lung cancer. Others smoke cigarettes all their lives and do not develop lung cancer. Thus, cigarettes are not what we call a sufficient cause of lung cancer.

The fact that not every smoker develops lung cancer implies that there must be factors that protect some individuals from lung cancer. The fact that some nonsmokers develop lung cancer implies that there must be additional contributory causes of lung cancer. Thus, the existence of a contributory cause implies that the “cause” increases the chances that the “effect” will develop. Its presence does not guarantee that the disease will develop. In addition, the absence of cigarette smoking does not guarantee that the disease will not develop. Despite the fact that cigarettes have been established as a contributory cause of lung cancer, they are

---

1 A relative risk of 10 does not tell us the absolute risk. The absolute risk is the actual chance or probability of developing the disease (lung cancer) in the presence of the risk factor (cigarette smoking), expressed numerically—for example, as 0.03 or 3%. A relative risk of 10 might imply an increase from 1 in 1000 individuals to 1 in 100 individuals. Alternatively, it might imply an increase from 1 in 100 individuals to 1 in 10 individuals. A relative risk can be calculated whenever we have data on groups of individuals; therefore, it does not in and of itself imply that a contributory cause is present. We need to be careful not to imply that the risk factor will increase the chances of developing the disease or that reducing or eliminating the risk factor will reduce or eliminate the disease unless we have evidence of contributory cause. For case-control studies, a measure known as the odds ratio can be calculated and is often used as an approximation of relative risk.

6 A dose-response relationship may also imply that greater exposure to a factor is associated with reduced probability of developing the disease, such as with exercise and coronary artery disease. In this case, the factor may be called a protective factor rather than a risk factor.
### TABLE 2.1 Supportive or Ancillary Criteria—Cigarettes and Lung Cancer

<table>
<thead>
<tr>
<th>Criteria</th>
<th>Meaning of the criteria</th>
<th>Evidence for cigarettes and lung cancer</th>
<th>Cautions in using criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td>Strength of the relationship</td>
<td>The risk for those with the risk factor is greatly increased compared to those without the risk factor.</td>
<td>The relative risk is large or substantial. The relative risk is greater than 10 for the average smoker, implying that the average smoker has more than 10 times the probability of developing lung cancer compared to nonsmokers.</td>
<td>Even relatively modest relative risks may make important contributions to disease when the risk factor is frequently present. A relative risk of 2, for instance, implies a doubling of the probability of developing a disease.</td>
</tr>
<tr>
<td>Dose-response relationship</td>
<td>Higher levels of exposure and/or longer duration of exposure to the “cause” are associated with increased probability of the “effect.”</td>
<td>Studies of cigarettes and lung cancer establish that smoking half a pack a day over an extended period of time increases the risk compared to not smoking. Smoking one pack per day and two packs per day further increase the risk.</td>
<td>No dose-response relationship may be evident between no smoking and smoking one cigarette a day or between smoking three and four packs per day.</td>
</tr>
<tr>
<td>Consistency of the relationship</td>
<td>Studies at the individual level produce similar results in multiple locations among populations of varying socioeconomic and cultural backgrounds.</td>
<td>Hundreds of studies in multiple locations and populations consistently establish an individual association between cigarettes and lung cancer.</td>
<td>Consistency requires the availability of numerous studies that may not have been conducted.</td>
</tr>
<tr>
<td>Biological plausibility</td>
<td>Known biological mechanisms can convincingly explain a cause-and-effect relationship.</td>
<td>Cigarette smoke directly reaches the areas where lung cancer appears.</td>
<td>Exactly which component(s) of cigarette smoking produce lung cancer are just beginning to be understood.</td>
</tr>

**BOX 2.5 Words that Imply Causation**

Often when reading the newspaper or other media, you will find that conclusions about cause and effect are made based upon far less rigorous examination of the data than we have indicated are needed to definitively establish cause and effect. In fact, we often draw conclusions about cause and effect without even consciously recognizing we have done so. Our language has a large number of words that imply a cause-and-effect relationship, some of which we use rather casually.

Let us take a look at the many ways that a hypothetical newspaper article might imply the existence of a cause-and-effect relationship or a contributory cause even when the evidence is based only upon a group association or upon speculation about the possible relationships.

Over several decades, the mortality rates from breast cancer in the United States were observed to increase each year. This trend was due to and can be blamed on a variety of factors, including the increased use of estrogens and exposure to estrogens in food. The recent reduction in breast cancer resulted from and can be attributed to the declining use of estrogens for menopausal and postmenopausal women. The declining mortality rate was also produced by the increased use of screening tests for breast cancer that were responsible for early detection and treatment. These trends demonstrate that reduced use of estrogens and increased use of screening tests have contributed to and explain the reduction in breast cancer.

While these conclusions sound reasonable and may well be cause-and-effect relationships, note that they rely heavily on assertions for which there is no direct evidence provided. For instance, the following words are often used to imply a cause-and-effect relationship when evidence is not or cannot be presented to support the relationship:

- due to
- blamed on
- result from
- attributable to
- produced by
- responsible for
- contributed to
- explained by

It is important to be aware of conscious or unconscious efforts to imply cause-and-effect relationships when the data suggests only group associations and does not meet our more stringent criteria establishing cause and effect.
not a necessary or a sufficient cause of lung cancer. In fact, the use of the concept of necessary and sufficient cause is not considered useful in the evidence-based public health approach because so few, if any, diseases fulfill the definitions of necessary and sufficient cause. These criteria are too demanding to be used as standards of proof in public health or medicine.

By 1964, the evidence that cigarette smoking was a contributory cause of lung cancer was persuasive enough for the surgeon general of the United States to produce the first surgeon general’s Report on Smoking and Health. The report concluded that cigarettes are an important cause of lung cancer. Over the following decades, the surgeon general’s reports documented the evidence that cigarette smoking causes not only lung cancer, but also other cancers—including cancer of the throat and larynx. Cigarette smoking is also a contributory cause of chronic obstructive pulmonary disease (COPD) and coronary artery disease. Smoking during pregnancy poses risks to the unborn child, and passive or secondhand smoke creates increased risks to those exposed—especially children. Based on the surgeon general’s findings, there is clearly overwhelming evidence that cigarette smoking is a contributory cause of lung cancer and a growing list of other diseases. Thus, let us turn our attention to the third component of the P.E.R.I.E. process: recommendations.

**Recommendations: What Works to Reduce the Health Impact?**

The evidence for cigarette smoking as a cause of lung cancer, as well as other diseases, was so strong that it cried out for action. In evidence-based public health, however, action should be grounded in recommendations that incorporate evidence. That is, evidence serves not only to establish contributory cause, but is also central to determining whether or not specific interventions work.

Evidence-based recommendations are built upon the evidence from studies of interventions. Thus, recommendations are summaries of the evidence about which interventions work to improve health outcomes. They indicate whether action should be taken. Evidence-based recommendations utilize the same types of investigations we discussed for contributory cause. In fact, the requirements of contributory cause are the same as those for establishing that an intervention works or has efficacy for the particular population that was studied. Evidence-based recommendations, however, go beyond efficacy or benefits and also take into account harms or safety.

In the decades since the surgeon general’s initial report, a long list of interventions has been implemented and evaluated. The term “intervention” is a very broad term in public health. Interventions range from individual counseling and prescription of pharmaceutical drugs that aid smoking cessation; to group efforts, such as peer support groups; to social interventions, such as cigarette taxes and legal restrictions on smoking in restaurants.

Recommendations for action have been part of public health and medicine for many years. Evidence-based recommendations, however, are relatively new. They have been contrasted with the traditional eminence-based recommendation, which uses the opinion of a respected authority as its foundation. Evidence-based recommendations ask about the research evidence supporting the benefits and harms of potential interventions. In evidence-based recommendations, the opinions of experts are most important when research evidence does not or cannot provide answers.

Before looking at the evidence-based recommendations on cigarette smoking made by the Centers for Disease Control and Prevention (CDC), let us look at how they are developed and graded. Evidence-based recommendations are based upon two types of criteria: the quality of the evidence and the magnitude of the impact. Each of these criteria is given what is called a score. The quality of the evidence is scored based in large part upon the types of investigations and how well the investigation was conducted. Well-conducted randomized controlled trials that fully address the health problem are considered the highest quality evidence. Often, however, cohort and case-control studies are needed and are used as part of an evidence-based recommendation.

Expert opinion, though lowest on the hierarchy of evidence, is often essential to fill in the holes in the research evidence. The quality of the evidence also determines whether the data collected during an intervention are relevant to its use in a particular population.
or setting. Data from young adults may not be relevant to children or the elderly. Data from severely ill patients may not be relevant to mildly ill patients. Thus, high-quality evidence needs to be based not only on the research, which can establish efficacy in one particular population, but also on the effectiveness of the intervention in the specific population in which it will be used.

In evidence-based public health, the quality of the evidence is often scored as good, fair, or poor. Good quality implies that the evidence fulfills all the criteria for quality. Poor quality evidence implies that there are fatal flaws in the evidence and recommendations cannot be made. Fair quality lies in between having no fatal flaws and fulfilling all the criteria for quality.\(^h\)

In addition to looking at the quality of the evidence, it is also important to look at the magnitude of the impact of the intervention. The magnitude of the impact asks the question: How much of the disability and/or death due to the disease can be potentially removed by the intervention? In measuring the magnitude of the impact, evidence-based recommendations take into account the potential benefits of an intervention, as well as the potential harms. Therefore, we can regard the magnitude of the impact as the benefits minus the harms, or the “net benefits.”\(^i\)

The magnitude of the impact, like the quality of the evidence, is scored based upon a limited number of potential categories. In one commonly used system, the magnitude of the impact is scored as substantial, moderate, small, and zero/negative.\(^i\) A substantial impact may imply that the intervention works extremely well for a small number of people, such as a drug treatment for cigarette cessation. These are the types of interventions that are often the focus of individual clinical care. A substantial impact may also imply that the intervention has a modest net benefit for any one individual, but can be applied to large numbers of people, such as through media advertising or taxes on cigarettes. These are the types of interventions that are most often the focus of traditional public health and social policy.

Evidence-based recommendations combine the score for the quality of the evidence with the score for the magnitude of the impact.\(^i\) TABLE 2.3 summarizes how these aspects can be combined to produce a classification of the strength of the recommendation, graded as A, B, C, D, and I.

It may be useful to think of these grades as indicating the following:

\[
A = \text{Must—A strong recommendation.}
\]

\[
B = \text{Should—A recommendation}
\]

\[
C = \text{Consider—A weak recommendation.}
\]

\[
D = \text{May—A recommendation}
\]

\[
I = \text{Expert opinion—A recommendation based on expert opinion.}
\]

\[
	ext{Poor (insufficient evidence) I I I I}
\]

\[
	ext{No fatal flaws and fulfilling all the criteria for quality.}
\]

\[
	ext{The magnitude of the impact can be measured using the relative risk calculation.}
\]

\[
	ext{Net benefit: A B C D}
\]

\[
	ext{Net benefit: moderate}
\]

\[
	ext{Net benefit: small}
\]

\[
	ext{Net benefit: zero/negative}
\]

\[
	ext{Data from Agency for Healthcare Research and Quality, U.S. Preventive Services Task Force Guide to Clinical Preventive Services Vol 1, AHRQ Pub. No.02-500.}
\]

h To fulfill the criteria for good quality data, evidence is also needed to show that the outcome being measured is a clinically important outcome. Short-term outcomes called surrogate endpoints, or surrogate outcomes, such as changes in laboratory tests, may not reliably indicate longer term or clinically important outcomes.

i The magnitude of the impact can be measured using the relative risk calculation. When dealing with interventions, the people who receive the intervention are often placed in the numerator. Thus, an intervention that reduces the bad outcomes by half would have a relative risk of 0.5. The smaller the relative risk is, the greater the measured impact of the intervention. If the relative risk is 0.20, then those with the intervention have only 20% of the risk remaining. Their risk of a bad outcome has been reduced by 80%. The reduction in a bad outcome is called the attributable risk percentage or, if a contributory cause is present, the percent efficacy. The intervention can only be expected to accomplish this potential reduction in risk when a contributory cause is present and the impact of the “cause” can be immediately and completely eliminated.
B = Should—In general, the intervention should be used unless there are good reasons or contraindications for not doing so.

C = May—The use of judgment is often needed on an individual-by-individual basis. Individual recommendations depend on the specifics of an individual's situation, risk-taking attitudes, and values.

D = Don’t—There is enough evidence to recommend against using the intervention.

I = Indeterminant, insufficient, or "I don't know"—The evidence is inadequate to make a recommendation for or against the use of the intervention at the present time.

Notice that evidence-based public health and medicine rely primarily on considerations of benefits and harms. However, recently issues of financial cost have begun to be integrated into evidence-based recommendations. At this point, however, cost considerations are generally only taken into account for "close calls." Close calls are often situations where the net benefits are small to moderate and the costs are large.

The evidence-based public health approach increasingly relies on the use of evidence-based recommendations that are graded based on the quality of the evidence and the expected impact of the intervention. The recommendations are made by a wide array of organizations, as discussed in BOX 2.6. It is important to appreciate the source of the recommendations, as well as the methods used to develop them.

Let us take a look at some examples of how interventions to prevent smoking, detect lung cancer early, or cure lung cancer have been graded. The CDC publishes “The Guide to Community Preventive Services,” commonly referred to as “The Community Guide.” This guide indicates that the following interventions are recommended, implying a grade of A or B:

- Clean indoor air legislation, prohibiting tobacco use in indoor public and private workplaces
- Federal, state, and local efforts to increase taxes on tobacco products as an effective public health intervention to promote tobacco use cessation and to reduce the initiation of tobacco use among youths
- The funding and implementation of long-term, high-intensity mass media campaigns using paid broadcast times and media messages developed through formative research
- Proactive telephone cessation support services (quit lines)
- Reduced or eliminated copayments for effective cessation therapies
- Reminder systems for healthcare providers (encouraging them to reinforce the importance of cigarette cessation)
- Efforts to mobilize communities to identify and reduce the commercial availability of tobacco products to youths

Additional recommendations encourage clinicians to specifically counsel patients against smoking,

**BOX 2.6 Who Develops Evidence-Based Recommendations?**

Evidence-based recommendations may be developed by a range of groups, including the government, practitioner-oriented organizations, consumer-oriented organizations, organized healthcare systems, and even for-profit organizations. Organizations developing evidence-based recommendations, however, are expected to acknowledge their authorship and identify the individuals who participated in the process, as well as their potential conflicts of interest. In addition, regardless of the organization, the evidence-based recommendations should include a description of the process used to collect the data and make the recommendations.

For-profit organizations may make evidence-based recommendations. However, their obvious conflicts of interest often lead them to fund other groups to make recommendations. Thus, the funding source(s) supporting the development of evidence-based recommendations should also be acknowledged as part of the report.

One well-regarded model for the development of evidence-based recommendations is the task force model used by the United States Preventive Services Task Force of the Agency for Healthcare Research and Quality (AHRQ), as well as by the Task Force on Community Preventive Services of the CDC. The task force model aims to balance potential conflicts of interest and ensures a range of expertise by selecting a variety of experts, as well as community participants, based upon a public nomination process. Once the task force members are appointed, their recommendations are made by a vote of the task force, and do not require approval by the government agency.

As a reader of evidence-based recommendations, it is important that you begin by looking at which group developed the recommendations, whether they have disclosed their membership, including potential conflicts of interest, and the groups’ procedures for developing the recommendations.
prescribe medications for adults, encourage support
groups for smoking cessation, and treat lung cancer
with the best available treatments when detected.

Of interest is the grade of D for recommending
against screening for early detection of lung cancer
using traditional chest X-rays. The evidence strongly
suggests that screening using this method may detect
cancer at a slightly earlier stage, but not early enough to
alter the course of the disease. Therefore, early detection
does not alter the outcome of the disease. Research con-
tinues to search for and identify better screening meth-
ods to detect lung cancer in time to make a difference.

Evidence-based recommendations are not the end
of the process. There may be a large number of recom-
endations among which we may need to choose. In
addition, we need to decide the best way(s) to put the
recommendations into practice. Thus, implementation
is not an automatic process. Issues of ethics, culture,
politics, and risk-taking attitudes can and should have
major impacts on implementation. A fourth step in the
evidence-based public health approach requires us to
look at the options for implementation and to develop
a strategy for getting the job done.

**Implementation: How Do We Get the Job Done?**

Strong recommendations based upon the evidence are
ideally the basis of implementation. At times, however,
it may not be practical or ethical to obtain the evidence
needed to establish contributory cause and develop
evidence-based recommendations. The process of
implementation itself may be part of the process of
establishing causation, as it was for cigarette smoking
in the 1960s when 100,000 physicians stopped smok-
ing and their rates of lung cancer declined rapidly, as
compared to other similar professionals who did not
stop smoking.

Today, there are often a large number of interven-
tions with adequate data to consider implementation.

Many of the interventions have potential harms,
as well as potential benefits. The large and growing
array of possible interventions means that health
decisions require a systematic method for decid-
ing which interventions to use and how to combine
them in the most effective and efficient ways. One
method for examining the options for implementa-
tion uses a structure we will call the “When-Who-
How” approach.

“When” asks about the timing in the course of
disease in which an intervention occurs. This timing
allows us to categorize interventions as primary,
secondary, and tertiary. **Primary interventions**
take place before the onset of the disease. They aim
to prevent the disease from occurring. **Secondary
interventions** occur after the development of a dis-
eease or risk factor, but before symptoms appear. They
are aimed at early detection of disease or reducing
risk factors while the individual is asymptomatic.
**Tertiary interventions** occur after the initial occur-
rence of symptoms, but before irreversible disability.
They aim to prevent irreversible consequences of
the disease. In the cigarette smoking and lung can-
cer scenario, primary interventions aim to prevent
cigarette smoking. Secondary interventions aim to
reverse the course of disease by smoking cessation
efforts or screening to detect early disease. Tertiary
interventions diagnose and treat diseases caused by
smoking in order to prevent permanent disability
and death.

“Who” asks: At whom should we direct the inter-
vention? Should it be directed at individuals one at a
time as part of clinical care? Alternatively, should it be
directed at groups of people, such as vulnerable popu-
lations, or should it be directed at everyone in a com-
munity or population?

Finally, we need to ask: How should we implement
interventions? There are three basic types of interven-
tions when addressing the need for behavioral change.
These interventions can be classified as information
(education), motivation (incentives), and obligation
(requirements).}

---

\[j\] The CDC defines four levels of intervention: the individual, the relationship (for example, the family), the community, and society or the population as a whole. This framework has the advantage of separating immediate family interventions from community interventions. The group or at-risk group relationship used here may at times refer to the family unit or geographic communities. It may also refer to institutions or at-risk vulnerable groups within the community. The use of group or at-risk group relationship provides greater flexibility, allowing application to a wider range of situations. In addition, the three levels used here correlate with the measurements of relative risk, attributable risk percentage, and population attributable percentage, which are the fundamental epidemiological measurements applied to the magnitude of the impact of an intervention.

\[k\] An additional option is innovation. Innovation implies a technical or engineering solution. A distinct advantage of technical or engineering solutions is that they often require far less behavior change. Changing human behavior is frequently difficult. Nonetheless, it is an essential component of most, if not all, successful public health interventions. Certainly, that is the case with cigarette smoking.
An information or education strategy aims to change behavior through individual encounters, group interactions, or the mass media. Motivation implies use of incentives for changing or maintaining behavior. It implies more than strong or enthusiastic encouragement—it implies tangible reward. Obligation relies on laws and regulations requiring specific behaviors. TABLE 2.4 illustrates how options for implementation for cigarette smoking might be organized using the “When-Who-How” approach. To better understand the “who” and “how” of the options for intervention when behavior change is needed, refer to TABLE 2.5, which outlines nine different options.

Deciding when, who, and how to intervene depends in large part upon the available options and the evidence that they work. It also depends in part on our attitudes toward different types of interventions. In U.S. society, we prefer to rely on informational or educational strategies. These approaches preserve freedom of choice, which we value in public, as well as private, decisions. Use of mass media informational strategies may be quite economical and efficient relative to the large number of individuals they reach, though messages, but they often need to be tailored to different audiences. However, information is often ineffective in accomplishing behavioral change—at least on its own.

Strategies based upon motivation, such as taxation and other incentives, may at times be more effective than information alone, though educational strategies are still critical to justify and reinforce motivational

</tr>
</tbody>
</table>
interventions. Motivational interventions should be carefully constructed and judiciously used, or they may result in what has been called victim blaming. For example, victim blaming in the case of cigarette smoking implies that we regard the consequences of smoking as the smokers’ own fault.

The use of obligation or legally required action can be quite effective if clear-cut behavior and relatively simple enforcement, such as restrictions on indoor public smoking, are used. These types of efforts may be regarded by some as a last resort, but others may see them as a key to effective use of other strategies. Obligation inevitably removes freedom of choice and if not effectively implemented with regard for individual rights, the strategy may undermine respect for the law. Enforcement may become invasive and expensive, thus obligation requires careful consideration before use as a strategy.

Understanding the advantages and disadvantages of each type of approach is key to deciphering many of the controversies we face in deciding how to implement programs to address public health problems; however, implementation is not the end of the evidence-based public health process. It is important to evaluate the success of an intervention in practice. Evaluation is the fifth and final component of the P.E.R.I.E. approach.

Evaluation: How Do We Evaluate Results?

Public health problems are rarely completely eliminated with one intervention—there are few magic bullets in this field. Therefore, it is important to evaluate whether an intervention or combination of interventions has been successful in reducing the problem. It is also critical to measure how much of the problem has been eliminated by the intervention(s) and what is the nature of the problem that remains.

Traditionally, evaluation has asked before and after questions. For instance, studies of cigarette smoking between the mid-1960s, when cigarettes were first declared a cause of lung cancer, and the late 1990s demonstrated that there was nearly a 50% reduction in cigarette smoking in the United States and that the rates of lung cancer were beginning to fall—at least among males. However, much of the problem still existed because the rates among adolescent males and females remained high and smoking among adults was preceded by smoking as adolescents nearly 90% of the time. Thus, an evaluation of the success of cigarette smoking interventions led to a new cycle of the process. It focused on how to address the issue of adolescent smoking and nicotine addiction among adults.

Many of the interventions being used today grew out of this effort to cycle once again through the evidence-based public health process and look for a new understanding of the problem, its etiology, evidence-based recommendations, and options for implementation.

The advent of e-cigarettes is again requiring us to utilize the P.E.R.I.E. framework to better understand their benefits and harms. E-cigarette research illustrates how public health research is being broadened to include not only traditional quantitative research but new methods of qualitative research. Roles of qualitative methods in public health research using e-cigarettes as an example is discussed in BOX 2.7.

In recent years, this process of evaluation has been extended to attempt to address how well specific interventions work and are accepted in practice. A new framework, called the RE-AIM framework, is increasingly being used to evaluate these factors. RE-AIM is a mnemonic that stands for reach, effectiveness, adoption, implementation, and maintenance. You can think of the "RE" factors as evaluating the potential of the intervention for those it is designed to include or reach as well as those it has the potential to reach in practice. It is important to recognize that interventions are often applied far beyond the groups for whom they have been designed or investigated.

The “AIM” factors examine the acceptance of the intervention in clinical or public health practice in the short and long term. TABLE 2.6 defines the meaning of each of these components and illustrates how a new

**BOX 2.7 Qualitative Data and Its Importance to Public Health**

Qualitative data can serve a variety of functions in public health. It can generate ideas or hypotheses for further study, provide key information on the reasons for success or failure of an intervention, and provide explanations for findings of quantitative research.

Quantitative research often includes a large sample and focuses on numbers, whereas qualitative research often looks in depth at a small sample, producing descriptions and allowing for a thorough exploration of the phenomenon of interest. Qualitative research on e-cigarettes may provide examples of the range of uses of qualitative research.

Focus groups and interviews are increasingly important forms of qualitative research that are being used to gain insight into how and why people come to conclusions or hold opinions on issues such as e-cigarettes. The opinions examined increasingly go beyond commercial products and politicians and include issues such as perceptions of the benefits and harms of e-cigarettes, access to e-cigarettes, and what interventions would be effective in controlling use of e-cigarettes in children.

Qualitative research may also help explain quantitative research findings. For instance qualitative research might conclude that e-cigarette use is growing among 16-18 year olds but not among 12-16 year olds. The insights provided by individuals of these ages may help explain these findings.

The ideas put forward by these types of qualitative research may generate new hypotheses to be examined using quantitative studies. They may also help assess barriers to implementation and suggest new approaches.

These and other approaches to qualitative research help generate new ideas or hypotheses, predict responses to new interventions, and help us better understand the reasons for the observed results of quantitative research. Qualitative and quantitative research should be seen as complementary, not competitive, as they can work together to provide greater insight and understanding.
hypothetical intervention for cigarette cessation might be evaluated using the RE-AIM framework.

Notice that the RE-AIM framework implies that successful interventions have been widely disseminated. That is, there has been widespread circulation of information often aimed at integration into public health and/or clinical practice. Dissemination, while not a separate component of the P.E.R.I.E. framework, is an expected and essential component of successful interventions.

Deciding the best combination of approaches to address a public health problem remains an important part of the judgment needed for the practice of public health. In general, multiple approaches are often needed to effectively address a complex problem like cigarette smoking. Population and high-risk group approaches, often used by public health professionals, and individual approaches, often used as part of health care, should be seen as complementary. Often using both types of interventions is more effective than either approach alone. Social interventions, such as cigarette taxes and restrictions on public smoking, are also important interventions to consider.

Today, an enormous body of evidence exists on the relationship between tobacco and health. Understanding the nature of the problems, the etiology or cause-and-effect relationships, the evidence-based
recommendations, and the approaches for implementing and evaluating the options for interventions remains key to the public health approach to smoking and health. FIGURE 2.3 diagrams the full P.E.R.I.E. approach.

TABLE 2.7 summarizes the questions to ask in the evidence-based public health approach.

The P.E.R.I.E. process summarizes the steps in evidence-based public health. It emphasizes the need to understand the nature of the problem and its underlying causes. It also helps structure the use of evidence to make recommendations and decide on which options to put into practice. Finally, the circular nature of the P.E.R.I.E. process reminds us that the job of improving health goes on, often requiring multiple efforts to understand and address the problem. Now that we have an understanding of the basic approach of evidence-based public health, let us turn our attention to the fundamental tools at our disposal for addressing public health problems.

**Discussion Questions**

1. Use the P.E.R.I.E. framework and the list of questions to outline how each step in the P.E.R.I.E. process was accomplished for cigarette smoking.

2. How would you use the P.E.R.I.E. process to address the remaining problem of cigarette smoking in the United States?

SECTION I

Cases and Discussion Questions
HIV/AIDS Determinants and Control of the Epidemic

A report appeared in the CDC’s “Morbidity and Mortality Weekly Report” (MMWR) on June 5, 1981, describing a previously unknown deadly disease in five young homosexual males, all in Los Angeles. The disease was characterized by dramatically reduced immunity, allowing otherwise innocuous organisms to become “opportunistic infections,” rapidly producing fatal infections or cancer. Thus, acquired immune deficiency syndrome (AIDS) first became known to the public health and medical communities. It was soon traced to rectal intercourse, blood transfusions, and reuse of injection needles as methods of transmission. Reuse of needles was a common practice in poor nations. It was also widespread among intravenous drug abusers. Within several years, the disease was traced to a previously unknown retrovirus, which came to be called the human immunodeficiency virus (HIV).

A test was developed to detect the disease and was first used in testing blood for transfusion. Within a short period of time, the blood supply was protected by testing all donated blood, and transmission of HIV by blood transfusion became a rare event. Diagnostic tests for HIV/AIDS soon became available for testing individuals. For many years, these were used by clinicians only for high-risk individuals. In recent years, HIV testing has become more widely used, as the testing no longer requires blood drawing and the results are rapidly available. The CDC has put increasing emphasis on testing as part of routine health care.

In subsequent years, much has been learned about HIV/AIDS. Today, it is primarily a heterosexually transmitted disease with greater risk of transmission from male to females than females to males. In the United States, African Americans are at the greatest risk. Condoms have been demonstrated to reduce the risk of transmission. Abstinence and monogamous sexual relationships likewise eliminate or greatly reduce the risk. Even serial monogamy reduces the risk compared to multiple simultaneous partners. Male circumcision has been shown to reduce the potential to acquire HIV infection by approximately 50%.

In major U.S. cities, the frequency of HIV is often greater than 1% of the population, fulfilling the CDC definition of “high risk.” In these geographic areas, the risk of unprotected intercourse is substantially greater than in most suburban or rural areas. Nearly everyone is susceptible to HIV infection, despite the fact that a small number of people have well documented protection on a genetic basis.

Maternal-to-child transmission is quite frequent and has been shown to be largely preventable by treatments during pregnancy and at the time of delivery. CDC recommendations for universal testing of pregnant women and intervention for all HIV-positive patients have been widely implemented by clinicians and hospitals and have resulted in greatly reduced frequency of maternal-to-child transmissions in the developed countries and in developing countries in recent years.

Medication is now available that greatly reduces the load of HIV present in the blood. These medications delay the progression of HIV and also reduce the ease of spread of the disease. These treatments were rapidly applied to HIV/AIDS patients in developed countries, but it required about a decade before they were widely used in most developing countries. Inadequate funding from developed countries and controversies over patent protection for HIV/AIDS drugs delayed widespread use of these treatments in developing countries.

New and emerging approaches to HIV prevention include use of antiviral medications during breastfeeding, postcoital treatments, and rapid diagnosis and follow-up to detect and treat those recently exposed.

Discussion Questions

1. Use the BIG GEMS framework to examine the factors in addition to infection that have affected the spread of HIV and the control or failure to control the HIV/AIDS epidemic.
2. What roles has health care played in controlling or failing to control the HIV/AIDS epidemic?
3. What roles has traditional public health played in controlling or failing to control the HIV/AIDS epidemic?
4. What roles have social factors (beyond the sphere of health care or public health) played in controlling or failing to control the HIV/AIDS epidemic?

The Aging Society

George Harwick, a middle-class American from what he calls the “heartland” was just turning 65 and was in good health. His good health, however, depended on daily treatment for high blood pressure, diabetes, and high cholesterol as well as regular check-ups for his declining kidney function. He was planning to retire when he reached what Social Security called full retirement age, which is gradually increasing, but
because Medicare begins at age 65 he was going to sign up now.

George's mother Harriet turned 90 last month, but all was not so well. On the day before her birthday she found herself lying on the bathroom floor in pain after slipping getting out of the shower. Her bones were not as strong as they used to be and she was soon on her way to the operating room to replace her hip. She was told that 25 years ago she would most likely have died from the fracture but now she was faced with months of rehabilitation and a long stay in a rehabilitative facility. She wondered what would come next.

The United States is increasingly faced with what might be regarded as the price of its success. New technology is keeping the elderly like Harriet alive longer and the costs of health care for people like George is creating a financial crisis in Medicare.

The population of those over age 85 is growing faster than those of any other age group with those ages 65 to 85 trailing right behind. Those over 85 have been called the "frail elderly" because they are far more vulnerable to a range of diseases from strokes and heart disease, to falls and fractures, to Alzheimer's and Parkinson's disease. In the second decade of the 21st century there are less than 10 million people over 85 in the United States. By 2050 that number is expected to exceed 20 million.

In part because of the services provided through Medicare plus the health innovations stimulated by NIH research, the baby boomer generation, now rapidly turning 65, is expected to live longer. The life expectancy of those turning 65 today has grown to an average of approximately 20 years compared to less than 10 years when Medicare was begun in the mid-1960s. That means that about half those turning 65 today will be alive at age 85 and many will live well into their 90s. Despite gradual increases in the Social Security retirement age from 65 to 67, with debate about still higher ages, the age for eligibility for Medicare has remained at 65.

The Harwicks were fortunate since their family did not have a history of Alzheimer's disease and Harriet's mind was quite clear despite her frailty. She was glad to take advantage of new systems of caring for the frail elderly ranging from "aging in place" to senior day care, to family respite services, to efforts encouraging the elderly to remain active in their communities.

The burdens of taking care of the frail elderly are increasingly falling on family members as societal seeks to limit costs. Family leave policies and tax benefits for caring for the elderly are policies which may help relieve this burden. Living alone can lead to loneliness, which is increasingly being recognized as a risk factor for deteriorating physical and mental status. Social interactions are key to good health in the elderly as well as their enjoyment of life.

Prevention takes on a different meaning for the frail elderly. Many traditional screening programs, such as routine PAP smears or routine testing for colon or breast cancer, no longer are being applied to the elderly, especially those over 85. Control of LDL cholesterol, blood sugar, high blood pressure, and smoking cessation remain high priorities.

Efforts to prevent falls and respond quickly when they do occur have become a high priority for prevention in the frail elderly. Keeping physically active helps to prevent blood clots and worsening osteoporosis. As with Harriet, emergency treatment of these conditions when they do occur is now high on the list of common clinical procedures.

The healthcare system is gradually adjusting to the need to provide special services for the frail elderly who are often unable to navigate the increasingly complex world of community services, health care, and health insurance. Health Navigators, sometimes called community health workers, patient navigators, or health insurance navigators, are becoming an important part of the health care and community health systems. Providing health services in the home or residence is increasingly recognized as an effective and efficient method for caring for the frail elderly.

What should we do about the cost of Medicare? Some have argued that coverage under Medicare should be limited to those procedures that are considered cost-effective; by which they usually mean the extra cost is worth the extra expenses. Cost effectiveness, however, is a tricky business with ethical considerations. For instance should the cost of feeding, housing and taking care of the elderly who receive extra years of life be considered in calculating the cost? Is it cost-effective to prevent lung cancer knowing that a rapid death from lung cancer avoids the high costs for care of future chronic illnesses which will surely occur in those who no longer die of lung cancer?

Many countries have tried rationing care as an approach to limiting the healthcare costs of the elderly. Rationing is the rule in many European countries where advancing age is in-and-of itself a contraindication or disqualification for expensive medical interventions ranging from kidney transplants, and even weight loss surgery. Overt rationing has been politically taboo in the United States where even the mention of treating older patients differently has resulted in the accusation of "death panels."

Some say economic growth is the way out of our bind. They argue that a larger economy means more tax revenue to pay for Medicare and other problems...
of the elderly. Taxing those who can afford to pay to ensure health care for those who can’t afford the costs is the answer according to others. Still others say better, more efficient healthcare delivery is what we need.

George listens to these debates. Yes, he says, there’s a crisis in Medicare coming but that’s not my problem, I paid into the system for over 40 years and now my mother and I deserve to get what we are entitled to. I’ll fight and vote for those benefits until the day I die.

**Discussion Questions**

1. What makes the frail elderly different from other older individuals? Explain.
2. What health professionals and non health professional are needed to care for the frail elderly? Explain.
3. What types of costs should we consider when deciding whether a health service is “cost-effective”? Explain.
4. Would raising the Medicare eligibility age help or would it just leave large number of retirees without healthcare coverage? Explain.
5. Do you favor economic growth, taxing those who can afford to pay, or a more efficient healthcare system as the primary means to pay for the future Medicare system? Explain.

### Smoking and Adolescents—The Continuing Problem

The rate of smoking in the United States has been reduced by approximately one-half since the 1960s. However, the rate of smoking among teenagers increased in the 1980s and 1990s, especially among teenage females. This raised concerns that young women would continue smoking during pregnancy. In addition, it was found that nearly 90% of adults who smoked started before the age of 18, and in many cases at a considerably younger age.

In the 1980s and most of the 1990s, cigarette smoking was advertised to teenagers and even preteens, or “tweens,” through campaigns such as Joe Camel. In recent years, a series of interventions directed at teenagers and tweens was put into effect. These included elimination of cigarette vending machines, penalties for those who sell cigarettes to those under 18, and elimination of most cigarette advertising aimed at those under 18. In addition, the Truth Campaign aimed to convince adolescents, who often see smoking as a sign of independence from their parents, that not smoking is actually a sign of independence from the tobacco companies who seek to control their behavior. Evaluation studies concluded that these interventions have worked to reduce adolescent smoking by about one-third.

Despite the successes of the early years of the 2000s in lowering the rates of cigarette smoking among adolescents, the rates have now stabilized at over 20%. Evidence indicates that adolescents who smoke generally do not participate in athletics, more often live in rural areas, and are more often white and less often African American. Males and females smoke about the same amount overall, but white females smoke more and Asian females smoke less than their male counterparts.

New drugs taken as pills have recently been shown to increase the rates of success in smoking cessation among adults despite side effects. This is not the situation in adolescents because of increased potential for adverse effects, including suicide. A series of interventions has been suggested for addressing the continuing problem of adolescent smoking. These include:

- Expulsion from school for cigarette smoking
- Focus on adolescents in tobacco warning labels
- Selective use of nicotine gum and patches to help with withdrawal
- No smoking rules for sporting events, music concerts, and other adolescent-oriented events
- Fines for adolescents who falsify their age and purchase cigarettes
- Higher taxes on tobacco products
- Rewards to students in schools with the lowest smoking rates in a geographic area
- Higher auto insurance premiums for adolescents who smoke
- Application of technology to reduce the quantity of nicotine allowed in tobacco products to reduce the potential for addiction
- Testing of athletes for nicotine and exclusion from competition if they test positive
- Provision of tobacco counseling as part of medical care covered through insurance

The National Academy of Medicine has recommended that the age for purchase of cigarettes be raised from 18 to 21 years.a

**Discussion Questions**

1. How does this case illustrate the P.E.R.I.E. process?
2. Which of these interventions do you think would be most successful? Explain.
3. How would you classify each of these potential interventions as education (information),

---

a The National Academy of Medicine was previously known as the Institute of Medicine.
motivation (incentives), obligation (required), or innovation (technological change)?

4. What other interventions can you suggest to reduce adolescent smoking?

### Reye's Syndrome: A Public Health Success Story

Reye's Syndrome is a potentially fatal disease of childhood that typically occurs in the winter months at the end of an episode of influenza, chicken pox, or other acute viral infection. It is characterized by progressive stages of nausea and vomiting, liver dysfunction, and mental impairment that progress over hours to days and result in a range of symptoms, from irritability to confusion to deepening stages of loss of consciousness. Reye's Syndrome is diagnosed by putting together a pattern of signs and symptoms. There is no definitive diagnostic test for the disease.

Reye's Syndrome was first defined as a distinct condition in the early 1960s. By the 1980s, over 500 cases per year were being diagnosed in the United States. When Reye's Syndrome was first diagnosed, there was over a 30% case-fatality rate. Early diagnosis and aggressive efforts to prevent brain damage were shown to reduce the deaths and limit the mental complications, but there is no cure for Reye's Syndrome.

In the late 1970s and early 1980s, a series of case-control studies compared Reye's Syndrome children with similar children who also had an acute viral infection, but did not develop the syndrome. These studies suggested that use of aspirin, then called "baby aspirin," was strongly associated with Reye's Syndrome, with over 90% of those children afflicted with the syndrome having recently used aspirin.

Cohort studies were not practical because they would require observing very large numbers of children who might be given or not given aspirin by their caretakers. Randomized controlled trials were neither feasible nor ethical. Fortunately, it was considered safe and acceptable to reduce or eliminate aspirin use in children because there was a widely used alternative—acetaminophen (often sold under the brand name Tylenol)—that was not implicated in the studies of Reye's Syndrome.

As early as 1980, the CDC cautioned physicians and parents about the potential dangers of aspirin. In 1982, the U.S. surgeon general issued an advisory on the danger of aspirin for use in children. By 1986, the U.S. Food and Drug Administration required a Reye's Syndrome warning be placed on all aspirin-containing medications. These efforts were coupled with public service announcements, informational brochures, and patient education by pediatricians and other health professionals who cared for children. The use of the term "baby aspirin" was strongly discouraged.

In the early 1980s, there were over 500 cases of Reye's Syndrome per year in the United States. In recent years, there have often been fewer than 5 per year. The success of the efforts to reduce or eliminate the use of "baby aspirin" and the subsequent dramatic reduction in the frequency of Reye's Syndrome provided convincing evidence that aspirin was a contributory cause of the condition and its removal from use was an effective intervention.

### Discussion Questions

1. How does the Reye's Syndrome history illustrate the use of each of the steps in the P.E.R.I.E. process?
2. What unique aspects of Reye's Syndrome made it necessary and feasible to rely on case-control studies to provide the evidence to help reduce the frequency of the syndrome?
3. What types of methods for implementation were utilized as part of the implementation process? Can you classify them in terms of when, who, and how?
4. How does the Reye's Syndrome history illustrate the use of evaluation to demonstrate whether the implementation process was successful?

### Sudden Infant Death Syndrome (SIDS)

Sudden infant death syndrome, or SIDS, was first recognized as a distinct public health problem in the late 1960s when over 7000 infants each year were found to die suddenly and unexpectedly. “Crib deaths” have been recognized for centuries, but until they were formally recorded and investigated, little was known about their cause, leading some to conclude that intentional or unintentional suffocation by parents or caregivers played an important role.

Data from the investigations of SIDS indicated that the syndrome was very rare before babies' first month of life, increased during the second month, and peaked during the third month, before rapidly declining in frequency to again become rare after the fourth month of life. The timing of SIDS suggested that the condition occurs after infants begin to sleep for extended periods but prior to the time in which children can raise themselves up and roll over on their abdomen.
their own. Additional evidence suggested a seasonal trend, with more cases of SIDS occurring during cold weather months than during warm weather months.

In the 1980s, several case-control studies of SIDS cases and similar infants without SIDS established that infants who slept on their stomachs were at substantially increased risk of dying from SIDS. The studies indicated that the chances increased 4–7 times, suggesting that if a cause-and-effect relationship exists, a clear majority of SIDS cases could be prevented if infants slept on their back. Many parents and clinicians remained skeptical because the traditional teaching emphasized sleeping prone, or on the stomach, to reduce the possibility of choking on regurgitation and vomit. Despite the lack of evidence for this hazard, generations had been raised on this practice and belief.

Additional evidence of the effectiveness of a “back-to-sleep” intervention was provided by the experience of New Zealand, which was the first country to begin a program to encourage caretakers to put infants to sleep on their backs. The rates of SIDS in New Zealand declined rapidly in parallel with the increased rate at which infants were put to sleep on their back. Similar declines in SIDS did not occur in other countries that had not yet instituted similar back-to-sleep programs.

In 1992, the American Academy of Pediatrics made a recommendation that infants be placed on their back to sleep. The initial recommendations also endorsed side sleeping. In 1994, with the support of the American Academy of Pediatrics, the National Institutes of Health (NIH), and the U.S. Public Health Service, the Back-to-Sleep campaign was launched. The educational campaign included public service announcements, brochures and other publications, including information accompanying new cribs, plus efforts for pediatricians and others who care for infants to educate parents and caretakers about the importance of having infants sleep on their backs.

The frequency of infants sleeping prone in the United States was found by survey data to be reduced from approximately 70% to less than 15% during the years immediately following the initiation of the Back-to-Sleep campaign. During these years, the rates of SIDS fell by approximately 50%, an impressive change but less than expected by the initial data. The rate of prone sleeping among African Americans was found to be over twice as high as the rate among whites, and African American infants continued to have higher rates of SIDS than whites.

Continuing studies suggested that the side position was being commonly used. It was found that many infants moved from the side to the prone position, and movement from the side to the prone position carried a high risk of SIDS. Additional case-control studies suggested that soft objects and loose bedding as well as overheating were associated with SIDS. These relationships are consistent with the initial finding of an increase of SIDS in colder weather months.

Studies of the infants who slept on their back indicated an increasing in flattening of the head, or plagiocephaly. These changes were shown to be reduced by increasing the amount of “tummy time,” or play periods in which infants are placed prone under supervision. Guidelines for tummy time are now part of the evidence-based recommendations. SIDS continues to be an important cause of infant mortality, and new contributory causes continue to be investigated. SIDS reflects the use of evidence-based public health and the importance of continuing to study and develop new approaches to public health problems.

**Discussion Questions**

1. Discuss how the problem description component of the evidence-based public health approach suggested hypotheses for the etiology of SIDS.
2. Discuss the types of evidence used to support the relationship between sleeping prone and SIDS as well as the limitations of the evidence.
3. Discuss how the evidence-based recommendations incorporated potential benefits and harms.
4. Discuss how implementation and evaluation worked to establish sleeping on the back as a standard intervention to prevent SIDS.
5. Discuss how the continuing presence of the problem of SIDS produced a new round of use of the evidence-based public health approach.
